Jenna Zeigen • @zeigenvector

So, what ***does*** happen when you type www.google.com into the browser?

The OSI model is a really good way of thinking about processes like these. It details seven layers, from Layer 1 which talks about physical bits in the computer, through Layer 7, which is the full application layer, so things like the browser. This talk is going to start at Layer 4, which is transport. We won't be talking about anything lower than that, so no networking, though I'm sure there's plenty of stuff all over the Internet if you want to learn more about those lower layers.

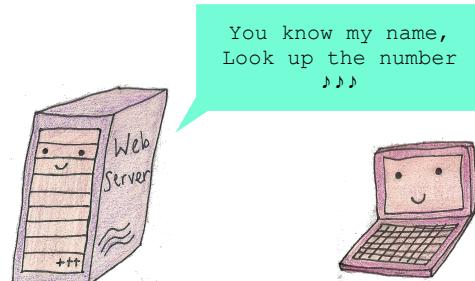

Overview

1. IP Address Lookup
2. Opening a socket
3. Security Stuff
4. HTTP Request
5. Server Things
6. HTTP Response
7. Parsing
8. Rendering

Jenna Zeigen • @zeigenvector

I'm going to go through all of these and talk about optimizations along the way!

IP Address Lookup

Jenna Zeigen • @zeigenvector

To do anything, we need to map the human readable URL "www.google.com" to the address of a computer to "talk to."

IP Address Lookup

Jenna Zeigen • @zeigenvector

First, the browser checks its cache.

IP Address Lookup

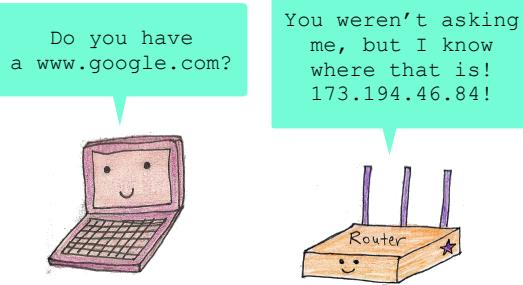

If not found, the browser calls the `gethostbyname` library function, the contents of which vary by OS, to do the lookup. This function checks if the hostname can be resolved by reference in the local hosts file, the location of which also varies by OS. On Macs, it's at `/etc/hosts`. This is how your computer knows what localhost should resolve to. If you wanna check it out, you can type `cat /etc/hosts` into your terminal and see what's in there!

IP Address Lookup

If `gethostbyname` does not have it cached and can't find it in the hosts file, then it makes a request to the DNS server configured in the network stack. This is typically the ISP's caching DNS server, but you could configure your computer to use any DNS server, i.e. Google's (8.8.8.8) if you wanted...

IP Address Lookup

The browser then kicks off a request to get the IP address for `www.google.com`, which goes through the local router, which also checks its cache.

IP Address Lookup

(Big thanks to @jedschmidt for this witty commentary)

IP Address Lookup

If the local router doesn't have anything cached, the browser ends up hitting the local ISP DNS server. This process uses UDP (User Datagram Protocol), or TCP if the request is too large.

UDP is kind of like the smallest bit of network you can use. It's great for unidirectional transactions, but delivery is not guaranteed in any order, or guaranteed at all. It's kind of like if you were to throw a bunch of balls at someone and hope that they catch them.

IP Address Lookup

Jenna Zeigen • @zeigenvector

When the name server comes back to the DNS server with the IP address answer, it will also come back with a TTL (time to live), an amount of time that the DNS server should cache the IP address. The longer the TTL, the faster this process, but then it's harder to change things. Historically, this TTL was 24 hours, which is why it could take up to 24 hours for the URL corresponding to an IP to change.

IP Address Lookup

The DNS server then responds to the client with the found IP address.

IP Address Lookup

The client then caches the IP address for next time. Some browsers also have their own DNS cache.

IP Address Lookup

If you want to check out this process hands-on, you can use the `dig` command in your terminal.

Opening a socket

Once the client has the IP address, it takes it and the port number from the URL, and makes a call to the system library function named `socket` and requests a TCP socket stream. We don't usually see port numbers on the end of URLs, but the HTTP protocol defaults to Port 80, and HTTPS to Port 443.

TCP stands for "Transmission Control Protocol." Unlike UDP, its job is to deliver a reliable, ordered, and error checked stream of packets across the network. It's more like a game of catch, to continue the ball metaphor. In fact, it's often called the "TCP handshake". TCP is the protocol that underlies HTTP, TLS, FTP, email, and SSH.

Opening a socket

The client then establishes TCP connection(s) with the server. It's kinda like this...

Opening a socket

Opening a socket

Opening a socket

Opening a socket

Well, more specifically like this...

1. The client sends a SYN packet with a randomly-selected sequence number "x"

2. The server replies with a SYN-ACK packet with an acknowledgement number set to "x+1" and a different randomly-selected sequence number "y"

Opening a socket

3. The client responds with an ACK packet, with the sequence number set to the received acknowledgement number " $x+1$ ", and a new acknowledgement number set to " $y+1$ "

Opening a socket

To prepare for the likely event that the client is going to need more things from the server, more than one connection will be opened.

TCP also has congestion control— requests start small and ramp up in size to make sure the network can support the requests. This is more of a relic from the past when networks weren't as reliable or fast.

In addition, TCP is where much the latency in this entire process comes from, as it's constrained by the speed of light. This is why it is advantageous to server assets from a server as close to your user as possible.

Opening a socket

♪ ♪

Jenna Zeigen • @zeigenvector

The server replies with a ServerHello message to the client with the TLS version, selected cipher, selected compression methods and the server's public certificate. The certificate contains a public key that will be used by the client to encrypt the rest of the handshake until a symmetric key can be agreed upon.

Security Stuff

The client verifies the server digital certificate. If trust can be established, the client generates a string of pseudo-random bytes and encrypts this with the server's public key.

Security Stuff

The server then decrypts the message and uses it to create its own version of the symmetric key.

Security Stuff

The client sends a Finished message to the server, encrypting a hash of the transmission up to this point with the symmetric key.

Security Stuff

The server generates its own hash, and then decrypts the client-sent hash to verify that it matches. If it does, it sends its own Finished message to the client, also encrypted with the symmetric key.

HTTP Request

With all this done, the client is ready to send an HTTP request to the server. HTTP stands for "HyperText Transfer Protocol." Unless the client and server negotiate using a more advanced version of HTTP, they're going to use HTTP/1.1.

HTTP/1.1 is stateless, uses a request/response model, and is a plain-text protocol.

HTTP Request

The client will send a request like this, containing the request and headers, followed by a single blank newline to the server indicating that the content of the request is done.

Jenna Zeigen • @zeigenvector

Before the formal parsing for rendering, the bytes get passed through a speculative parser, or look-ahead pre-parser. This parser looks ahead for external resources like JS, CSS, and image files so it can start getting them from the server immediately. If it finds them, it'll use the extra TCP requests, if they're from the same host. Otherwise, the client has to do the whole DNS dance again. This optimization wasn't always in the stack, but when released, improved page load performance by about 20%.

Meanwhile, the bytes are fed into the primary parser.

The parsing algorithm is described in detail by the HTML5 specification. It goes something like this:

1. The browser reads the raw bytes of the HTML off the disk or network and translates them to individual characters based on specified encoding of the file, e.g. UTF-8.
2. The characters get broken up into tags, e.g. html, head, and div.
3. The tags then then get made into nodes.
4. The nodes are then arranged into the DOM tree.

HTML Parsing

After this process, you end up with a DOM (Document Object Model) tree made from the HTML document. It has an almost one-to-one relationship with the markup.

HTML Parsing

Whatever, wherever

Once the browser has the asset, it then must parse and execute it before anything continues.

The big hiccup here is that browsers have imposed limits on how many parallel downloads you can have from the same domain. It used to be 2, but now that limit is anywhere from 6 to 13 in modern browsers, depending on the browser. This is a huge bottleneck, but many of the optimizations we hear about stem from trying to get around this. One thing you can do here is to serve your images from multiple hostnames, you can get around the same hostname parallel download limit.

Caching also comes into play here, because TTL in this case is determined by the headers sent with the asset, such as a far-future Expires header. This helps because the file does not need to be downloaded again, therefore not contributing to the download limit.

Jenna Zeigen • @zeigenvector

Another popular optimization is to combine your files together. This includes concatenating JavaScript and CSS files together using a tool like webpack, Gulp, or even the asset pipeline. However, this might come back to bite you with caching because overtime you change just one file in your bundle, the cache gets invalidated. Because of this, some developers have two bundles—one for application code that is likely to change often and one for vendor code that is less likely to change.

Another thing you can do is make CSS sprites or icon fonts so there aren't so many small images each with their own requests.

Some developers even inline their images as data:URIs.

Jenna Zeigen • @zeigenvector

CSS also does its own kind of blocking. It might seem that since CSS doesn't change the DOM tree, there's no reason to wait for it and stop the document parsing. There is an issue, though, of scripts asking for style information during the document parsing stage. If the styles aren't loaded and parsed yet, the scripts will get wrong answers and apparently this has caused lots of problems. It seems to be an edge case but is quite common.

Different browsers have different ways of dealing with this blocking though. Firefox blocks all scripts when there is a stylesheet that is still being loaded and parsed. WebKit blocks scripts only when they try to access certain style properties that may be affected by unloaded stylesheets.

CSS Parsing

Just doing that
browser thing...

Jenna Zeigen • @zeigenvector

Just like with HTML, the browser needs to convert the CSS file into something it can work with. Instead of making a DOM tree though, it makes a CSSOM tree! The CSS parser, unlike the HTML parser, is context-free, though the steps in the process are largely the same.

1 <!doctype html>
2 <html>
3   <head>
4     <script type="text/javascript" src="library.js"></script>
5     <link rel="stylesheet" type="text/css" href="styles.css">
6     <script type="text/javascript" src="website.js"></script>
7   </head>
8   <body>
9     <div>Let's pretend this is all of google</div>
10   </body>
11 </html>
```

Whoa, oh, oh, oh,
Whoa, oh, oh, oh,
The DOM's interactive
DOM's interactive
♪♪♪

Jenna Zeigen • @zeigenvector

When the HTML document is fully downloaded and parsed, the page is marked as "interactive" and the `DOMContentLoaded` event is fired, without waiting for all the assets to finish loading. At this point, you can click around the page—it's interactive!

HTML Parsing

Now that that was fired,
fired, fired,
We can load scripts marked
defer, 'fer, 'fer
♪♪♪

Jenna Zeigen • @zeigenvector

At this point, scripts marked with the `defer` attribute are executed.

HTML Parsing

In your eyes
The DOM's complete
♪♪♪

Jenna Zeigen • @zeigenvector

Finally, once every resource has been downloaded and parsed, the document is marked as complete, and the `load` event is fired.

HTTP/2

How you gonna upgrade me?
What's higher than one point one?
♪♪♪

Jenna Zeigen • @zeigenvector

HTTP/2 is a new HTTP specification that grew out of Google's work on SPDY ("speedy"). It serves to fix a bunch of the aspects of HTTP/1.1 that we need to optimize around all the time. So, once HTTP/2 is implemented across the board, most of the optimizations I discussed today will be obsolete. Features include:

- HTTP header compression (no repeated headers being passed back and forth)
- Server push technologies (sends assets with the HTML, because it knows you're gonna need it)
- Loading page elements in parallel over a single TCP connection

Overview

1. IP Address Lookup
2. Opening a socket
3. Security Stuff
4. HTTP Request
5. Server Things
6. HTTP Response
7. Parsing
8. Rendering
